PostgreSQL Multi-Database Integration Master Guide

This guide provides a complete, end-to-end workflow for connecting PostgreSQL databases hosted in Docker Desktop. We cover **Foreign Data Wrappers (FDW)**, **Cross-Database Relationships**, and **Schema-based Architectures**.

📋 Table of Contents

1. Prerequisites & Environment
2. Phase 1: Docker Infrastructure
3. Phase 2: The Two-Database Integration (FDW)
4. Phase 3: Security-First (Different Teams Workflow)
5. Phase 4: Resolving Foreign Key Conflicts (Soft Keys)
6. Phase 5: The High-Performance Alternative (Schemas)
7. Phase 6: Management via pgAdmin

---

1. Prerequisites & Environment

Create a project folder and a `.env` file to store your credentials.

File: `.env`

```
# Database 1 (Sales / Consumer)
DB1_NAME=sales_db
DB1_USER=sales_admin
DB1_PASS=sales_pass_123
DB1_PORT=5432

# Database 2 (Inventory / Provider)
DB2_NAME=inventory_db
DB2_USER=inventory_admin
DB2_PASS=inventory_pass_456
DB2_PORT=5433

# pgAdmin
PGADMIN_EMAIL=admin@example.com
PGADMIN_PASS=admin_pass
PGADMIN_PORT=8080
```

---

2. Phase 1: Docker Infrastructure

This `docker-compose.yml` sets up two independent database containers and pgAdmin on a shared internal network.

File: `docker-compose.yml`

```yaml
services:
  db1:
    image: postgres:16-alpine
    container_name: sales_container
    environment:
      POSTGRES_DB: ${DB1_NAME}
      POSTGRES_USER: ${DB1_USER}
      POSTGRES_PASSWORD: ${DB1_PASS}
    ports:
      - "${DB1_PORT}:5432"
    volumes:
      - sales_data:/var/lib/postgresql/data
    networks:
      - app_network

  db2:
    image: postgres:16-alpine
    container_name: inventory_container
    environment:
      POSTGRES_DB: ${DB2_NAME}
      POSTGRES_USER: ${DB2_USER}
      POSTGRES_PASSWORD: ${DB2_PASS}
    ports:
      - "${DB2_PORT}:5432"
    volumes:
      - inventory_data:/var/lib/postgresql/data
    healthcheck:
      test: ["CMD-SHELL", "pg_isready -U ${DB2_USER} -d ${DB2_NAME}"]
      interval: 5s
      timeout: 5s
      retries: 5
    networks:
      - app_network

  pgadmin:
    image: dpage/pgadmin4
    container_name: pgadmin_container
    environment:
      PGADMIN_DEFAULT_EMAIL: ${PGADMIN_EMAIL}
      PGADMIN_DEFAULT_PASSWORD: ${PGADMIN_PASS}
    ports:
      - "${PGADMIN_PORT}:80"
    depends_on:
      - db1
      - db2
```

```
    networks:
      - app_network

networks:
  app_network:
    driver: bridge

volumes:
  sales_data:
  inventory_data:
```

---

3. Phase 2: The Two-Database Integration (FDW)

This method allows `db1` to query `db2` directly. Execute these commands in **db1's Query Tool** in pgAdmin.

Step A: Enable Extension & Server

```
CREATE EXTENSION IF NOT EXISTS postgres_fdw;

-- Use 'db2' as the host because it's the Docker service name
CREATE SERVER inventory_server
FOREIGN DATA WRAPPER postgres_fdw
OPTIONS (host 'db2', port '5432', dbname 'inventory_db');
```

Step B: Create User Mapping

```
CREATE USER MAPPING FOR sales_admin
SERVER inventory_server
OPTIONS (user 'inventory_admin', password 'inventory_pass_456');
```

Step C: Selective Importing (Three Options)

Choose how much data you want to bring over:

1. **Import Only Specific Tables (Recommended):**

   ```
   CREATE SCHEMA remote_inventory;
   IMPORT FOREIGN SCHEMA public LIMIT TO (products, stock)
   FROM SERVER inventory_server INTO remote_inventory;
   ```

2. **Import Everything Except Specific Tables:**

```
IMPORT FOREIGN SCHEMA public EXCEPT (internal_logs, sensitive_data)
FROM SERVER inventory_server INTO remote_inventory;
```

3. **Manual Table Definition (Granular Column Control):**

```
CREATE FOREIGN TABLE remote_inventory.product_catalog (
    id int NOT NULL,
    product_name text
) SERVER inventory_server OPTIONS (schema_name 'public', table_name
'products');
```

---

4. Phase 3: Security-First (Different Teams Workflow)

If the databases are managed by different teams, follow this "Least Privilege" model.

1. On Inventory DB (The Provider Team)

Create a Read-Only user and only grant access to specific columns.

```
CREATE USER sales_team_reader WITH PASSWORD 'reader_pass';
GRANT USAGE ON SCHEMA public TO sales_team_reader;
-- Only grant access to the product name and price, hide secret costs!
GRANT SELECT (id, name, price) ON products TO sales_team_reader;
```

2. On Sales DB (The Consumer Team)

Update your User Mapping to use the restricted credentials.

```
CREATE USER MAPPING FOR sales_admin
SERVER inventory_server
OPTIONS (user 'sales_team_reader', password 'reader_pass');
```

---

5. Phase 4: Resolving Foreign Key Conflicts (Soft Keys)

Because **Physical Foreign Keys do not work across databases**, use one of these strategies.

Strategy 1: The Soft Key (Logical Relationship)

- **Database:** Define `product_id` as a standard `INTEGER` (no `REFERENCES`).
- **Application:** Your backend code (Python/Node) queries the Inventory DB to verify the product ID exists before saving the order in the Sales DB.

- **Safety:** Use **Soft Deletes** in the Inventory DB (`deleted_at` column) so the Sales DB never points to a missing ID.

Strategy 2: Trigger-Based Validation

Enforce the rule at the database level using FDW:

```
CREATE OR REPLACE FUNCTION check_inventory_id() RETURNS TRIGGER AS $$
BEGIN
    IF NOT EXISTS (SELECT 1 FROM remote_inventory.products WHERE id =
NEW.product_id) THEN
        RAISE EXCEPTION 'Product ID % does not exist in Inventory!',
NEW.product_id;
    END IF;
    RETURN NEW;
END; $$ LANGUAGE plpgsql;

CREATE TRIGGER trg_validate_order
BEFORE INSERT ON local_orders
FOR EACH ROW EXECUTE FUNCTION check_inventory_id();
```

---

6. Phase 5: The High-Performance Alternative (Schemas)

If you need **Strict Integrity (Hard Keys)** and **High Speed**, use one database container with multiple schemas.

1. Modified Structure

- **Database:** `app_db`
  - **Schema:** `sales`
  - **Schema:** `inventory`

2. Implementation SQL

```
CREATE SCHEMA inventory;
CREATE SCHEMA sales;

CREATE TABLE inventory.products (
    id SERIAL PRIMARY KEY,
    name TEXT NOT NULL
);

CREATE TABLE sales.orders (
    id SERIAL PRIMARY KEY,
    -- NATIVE FOREIGN KEY WORKS HERE!
    product_id INTEGER REFERENCES inventory.products(id) ON DELETE CASCADE,
    customer_name TEXT
);
```

```
-- Querying is seamless
SELECT * FROM sales.orders o JOIN inventory.products p ON o.product_id = p.id;
```

---

7. Phase 6: Management via pgAdmin

1. Open `http://localhost:8080`.
2. **Add Server 1:** Host: `db1`, User: `sales_admin`.
3. **Add Server 2:** Host: `db2`, User: `inventory_admin`.
4. **Verification:**
   - In `db1` -> `Foreign Servers`, you should see `inventory_server`.
   - In `db1` -> `Schemas` -> `remote_inventory` -> `Foreign Tables`, your linked tables should appear.

🚀 Summary: Which Option to Use?

Requirement	Recommendation
Strict Data Integrity (Hard Keys)	**Schemas** (One DB)
Microservices / Different Teams	**FDW** (Two DBs)
High Security / Column Masking	**FDW + Read-Only Mapping**
Simple Prototyping	**Soft Keys**

Addendum

To "redefine" a column as a Soft Key when you are in the **Sales Database** referring to the **Inventory Database**, you simply treat the ID as raw data (a standard `INTEGER`).

Because PostgreSQL cannot "reach out" across the network to verify a Foreign Key in real-time during a standard `INSERT`, you omit the `REFERENCES` clause entirely.

Here is exactly how you do it from the perspective of the **Consumer (Sales) Database**.

---

1. The SQL Definition (The "Soft Key")

When creating your local table in `sales_db`, you define the column type to match the remote ID (usually `INTEGER` or `UUID`), but you leave off the constraint.

```
-- Run this in SALES_DB
CREATE TABLE public.orders (
    order_id SERIAL PRIMARY KEY,

    -- REDEFINED: No 'REFERENCES inventory_db...' here!
    -- We call this a "Soft Key" or "Logical Key"
```

```
    product_id INTEGER NOT NULL,

    customer_name TEXT,
    quantity INTEGER
);
```

---

2. How you "Connect" them (The Join)

Even though there is no formal link in the table definition, you create the link **during the query** using the Foreign Data Wrapper (FDW) schema we set up earlier.

```
-- Querying from SALES_DB
SELECT
    o.order_id,
    o.customer_name,
    p.name AS product_name,  -- This comes from the OTHER database
    p.price                 -- This comes from the OTHER database
FROM public.orders o
JOIN remote_inventory.products p ON o.product_id = p.id;
```

---

3. How to "Simulate" the Reference (Integrity)

Since you don't have a `REFERENCES` constraint to stop users from entering a fake `product_id`, you have two ways to handle it from your side (the Sales DB):

Option A: The "Check" Trigger (Internal Validation)

If you want the Sales Database to error out if someone tries to insert a `product_id` that doesn't exist in the Inventory Database:

```
CREATE OR REPLACE FUNCTION validate_remote_product()
RETURNS TRIGGER AS $$
BEGIN
    -- Look into the FDW table to see if the ID exists
    IF NOT EXISTS (SELECT 1 FROM remote_inventory.products WHERE id =
NEW.product_id) THEN
        RAISE EXCEPTION 'Product ID % does not exist in the Inventory Database',
NEW.product_id;
    END IF;
    RETURN NEW;
END;
$$ LANGUAGE plpgsql;

CREATE TRIGGER trg_orders_product_check
BEFORE INSERT OR UPDATE ON public.orders
FOR EACH ROW EXECUTE FUNCTION validate_remote_product();
```

Option B: The Application Validation (External Validation)

If you are using a backend (Node, Python, PHP), your code handles the check:

1. **App:** `SELECT id FROM remote_inventory.products WHERE id = 50;`
2. **App:** If result is null, stop and show error.
3. **App:** If result exists, `INSERT INTO public.orders (product_id, ...) VALUES (50, ...);`

---

4. Pro-Tip: Naming Conventions

To make it clear to other developers that this `product_id` is a "Foreign" key that isn't enforced locally, many teams use a specific naming convention:

- Instead of `product_id`, name it `remote_product_id` or `ext_product_id`.
- Add a **comment** to the column in the database:

```
COMMENT ON COLUMN public.orders.product_id IS 'Soft Key: References
products(id) in inventory_db via FDW';
```

Summary of the "Redefinition"

1. **Type:** Must match the remote side (usually `INT`).
2. **Constraint:** Remove `REFERENCES ...`.
3. **Bridge:** Use the `JOIN` on the FDW table for reports.
4. **Enforcement:** Use a **Trigger** if you want the DB to handle it, or **App Logic** if you want your code to handle it.
5. **Naming Conventions:** To make it clear to other developers that this `product_id` is a "Foreign" key that isn't enforced locally, many teams use a specific naming convention:
   - Instead of `product_id`, name it `remote_product_id` or `ext_product_id`.
   - Add a **comment** to the column in the database:

     ```
     COMMENT ON COLUMN public.orders.product_id IS 'Soft Key: References
     products(id) in inventory_db via FDW';
     ```

   - Use a **View** to hide the complexity:

     ```
     CREATE VIEW public.orders_with_products AS
     SELECT
         o.order_id,
         o.customer_name,
         p.name AS product_name,
         p.price
     FROM public.orders o
     JOIN remote_inventory.products p ON o.product_id = p.id;
     ```

Integration from 'backupxxxx' file

To integrate a backup file into your Dockerized PostgreSQL setup, you need to follow a three-step process: **Upload**, **Restore**, and **Link**.

Since you have a backup file (let's call it `backup.sql` or `backup.dump`), we will restore it into **Database 2 (`db2`)** and then link it to **Database 1 (`db1`)**.

Step 1: Move the Backup into Docker

Docker containers cannot "see" files on your Windows/Mac desktop unless you move them or mount them.

Option A: The Command Line (Fastest) Open your terminal/command prompt in the folder where your backup file is located and run:

```
docker cp backupxxxx sales_container:/tmp/backupxxxx
```

(Replace `sales_container` with the `container_name` from your docker-compose for db2).

Option B: The Volume Folder If your `docker-compose` has a volume like `./db2_init:/docker-entrypoint-initdb.d`, just move the file into that folder on your computer. If it is a `.sql` file, Postgres will try to run it automatically when the container starts for the first time.

Step 2: Restore the Backup via pgAdmin

Once the file is "inside" the environment, use pgAdmin to restore it.

1. Open **pgAdmin**.
2. Right-click on your **Target Database** (e.g., `inventory_db` on `db2`).
3. Select **Restore**.
4. In the **Filename** field, click the folder icon.
    - If you used `docker cp`, look in `/tmp/`.
    - If you mapped a volume, look in the mapped path.
5. Select your file and click **Restore**.

> **Note:** If the backup was created using the "Plain" format in pgAdmin, use the **Query Tool** to open the file and hit **Play**. If it was "Custom" or "Tar" format, use the **Restore** menu.

Step 3: Create the Integration (The "Link")

Now that your data is living inside `db2`, you need to tell `db1` how to read it using the **Foreign Data Wrapper** method we discussed.

Run this in the Query Tool of `db1`:

```sql
-- 1. Enable the bridge tool
CREATE EXTENSION IF NOT EXISTS postgres_fdw;

-- 2. Define the server (use the docker service name 'db2')
CREATE SERVER restored_server
FOREIGN DATA WRAPPER postgres_fdw
OPTIONS (host 'db2', port '5432', dbname 'inventory_db');

-- 3. Map your credentials
CREATE USER MAPPING FOR sales_admin
SERVER restored_server
OPTIONS (user 'inventory_admin', password 'inventory_pass_456');

-- 4. Import the specific tables from the backup
-- IMPORTANT: Look at the restored database in pgAdmin.
-- If the backup created a schema named 'public', use 'public'.
-- If it created a schema named 'client_data', use that.
CREATE SCHEMA restored_data;

IMPORT FOREIGN SCHEMA public
LIMIT TO (table_name_from_backup)
FROM SERVER restored_server
INTO restored_data;
```

Step 4: Resolve the Foreign Key (Soft Key)

Now that the backup data is visible in `db1`, you can link your local tables to it.

If your backup contains a table of `products` and you want your local `orders` table to point to them:

1. **Check the ID type:** Look at the `id` column in `restored_data.products`. Is it an Integer? A UUID?
2. **Create your local table:**

```sql
CREATE TABLE local_orders (
    id SERIAL PRIMARY KEY,
    -- Redefine the product_id to match the backup's ID type
    backup_product_id INTEGER,
    customer_name TEXT
);
```

3. **Perform the Integration Join:**

```sql
SELECT
    o.customer_name,
    p.name as product_from_backup
FROM local_orders o
JOIN restored_data.products p ON o.backup_product_id = p.id;
```

Troubleshooting Common Backup Integration Issues:

- **Role Not Found:** If the backup was made from a database where the user was `boss_man`, and your Docker user is `admin`, the restore might show errors.
  - *Fix:* In the pgAdmin Restore dialog, go to **Restore options** and check **Do not save owner**.
- **Schema Confusion:** If your backup contains multiple schemas, you must run the `IMPORT FOREIGN SCHEMA` command for **each** schema you want to link.
- **Search Path:** If you want to query the restored tables easily without typing `restored_data.`, run:

  ```
  SET search_path TO public, restored_data;
  ```

Summary of the Workflow:

1. **Restore** the backup into the second container (`db2`).
2. **Link** the first container (`db1`) to the second using `postgres_fdw`.
3. **Map** the foreign tables into a local schema.
4. **Join** them using "Soft Keys" (Standard Integers) in your queries.

Scenario 1:

In this scenario, we treat the two databases as completely independent entities (representing two different teams or servers). Since you have a **pgAdmin backup file** for the Provider (DB2), we need to restore it first and then build the "bridge" from DB1.

Here is the step-by-step workflow:

Step 1: Restore the Backup to DB2 (The Provider)

Before DB1 can connect, DB2 must actually contain the data from your backup file.

1. **Open pgAdmin** and connect to your **DB2 Server**.
2. **Create a new database** named `inventory_db` (or whatever matches your backup).
3. **Right-click** the new database and select **Restore**.
4. **Upload/Select the File:**
   - Select your `backupxxxx` file.
   - *Note:* If the backup was created as a "Plain" SQL file, use the **Query Tool** to open and run it. If it's a `.backup` or `.dump` file, use the **Restore** menu.
5. **Clean up Roles (Important):** In the Restore options, check **"Do not save owner"** and **"Do not save privilege"**. This ensures the data is restored even if the original backup used different usernames.

Step 2: Prepare the Provider (DB2) for Integration

Once the data is restored, you must create a "door" for DB1 to enter through. You shouldn't give DB1 your admin password.

Run this in the DB2 Query Tool:

```
-- 1. Create a specific user for the Sales Team
CREATE USER sales_link_user WITH PASSWORD 'integration_password';

-- 2. Grant access to the schema where your backup data landed (usually 'public')
GRANT USAGE ON SCHEMA public TO sales_link_user;

-- 3. Grant SELECT access only to the tables they need
-- Replace 'products' with the name of the table from your backup
GRANT SELECT ON ALL TABLES IN SCHEMA public TO sales_link_user;
```

Step 3: Configure the Consumer (DB1) to Link to DB2

Now we go to the Sales Server (DB1) and tell it where the other server is located.

Run this in the DB1 Query Tool:

```
-- 1. Enable the Foreign Data Wrapper
CREATE EXTENSION IF NOT EXISTS postgres_fdw;

-- 2. Define the remote server
-- If using Docker: host is 'db2'. If truly separate servers: host is the IP
Address.
CREATE SERVER remote_inventory_server
FOREIGN DATA WRAPPER postgres_fdw
OPTIONS (host 'db2', port '5432', dbname 'inventory_db');

-- 3. Map your DB1 admin to the DB2 'sales_link_user'
CREATE USER MAPPING FOR sales_admin -- your local DB1 user
SERVER remote_inventory_server
OPTIONS (user 'sales_link_user', password 'integration_password');

-- 4. Create a schema to hold the "mirrored" tables
CREATE SCHEMA provider_data;

-- 5. Import the tables you want from the backup
IMPORT FOREIGN SCHEMA public
FROM SERVER remote_inventory_server
INTO provider_data;
```

Step 4: Verification (The Integration Query)

Now you can run a query in **DB1** that uses your local data and combines it with the restored data from the **DB2 Backup**.

```
SELECT
    l.order_id,
    l.customer_name,
    r.name AS product_name,
    r.price AS product_price
FROM local_orders l
JOIN provider_data.restored_table_name r ON l.product_id = r.id;
```

Critical Infrastructure Notes for "Two Separate Servers"

1. Docker Networking

In your `docker-compose.yml`, both services must be under the same `networks` block. If they are not on the same network, they cannot see each other by name (`db2`).

2. The pgAdmin Backup Format

If your backup file `backupxxxx` is a **Directory format** or **Custom format** (.dump), pgAdmin's Restore tool is required. If it is a **Plain format** (.sql), you can simply drag it into a Query Tool window and execute it.

3. Handling "Missing" Data during Restore

If your backup file references a schema that wasn't `public` (e.g., `production.products`), the `IMPORT FOREIGN SCHEMA` command in Step 3 must be updated:

```
IMPORT FOREIGN SCHEMA production -- Use the actual schema name from the backup
FROM SERVER remote_inventory_server
INTO provider_data;
```

4. Post-Restore Schema Updates

If you restore a new backup to DB2 later and the table structure changes (e.g., a new column was added), you **must** refresh the link in DB1:

```
DROP SCHEMA provider_data CASCADE;
CREATE SCHEMA provider_data;
IMPORT FOREIGN SCHEMA public FROM SERVER remote_inventory_server INTO
provider_data;
```

Summary of the "Backup Integration" Loop:

1. **DB2:** Restore `backupxxxx` file -> Create `sales_link_user` -> Grant `SELECT`.
2. **DB1:** `CREATE SERVER` -> `CREATE USER MAPPING` -> `IMPORT FOREIGN SCHEMA`.
3. **Result:** You can now treat the restored backup as a local schema in your primary database.

Scenerio 2:

---

if i restore the db2 backup in another schema but in the same server as db1, can i use foreign keys?

YES. If you restore the data from the DB2 backup into a **new schema** within the **same database** as DB1, you can use **Native Foreign Keys.**

In PostgreSQL, a "Database" is a hard boundary, but a "Schema" is just a logical folder. As long as the tables are in the same database (e.g., `app_db`), they can "see" and "lock" each other for referential integrity.

Why this is the "Pro" Move:

1. **Strict Integrity:** If you try to delete a product from the `inventory` schema that is still linked to an order in the `sales` schema, Postgres will stop you.
2. **Performance:** There is zero network overhead. No `postgres_fdw` is needed.
3. **Atomic Transactions:** You can update both schemas in one single transaction. If the inventory update fails, the sale is automatically rolled back.

Step-by-Step: How to do it

1. Restore the Backup into a Schema

When you restore a backup in pgAdmin, it usually tries to put everything into the `public` schema. To keep things clean, we will move the backup data into its own schema.

Method A: Using pgAdmin

1. Connect to your main database (e.g., `sales_db`).
2. Create a new schema: `CREATE SCHEMA inventory_schema;`
3. Right-click the database and select **Restore**.
4. In **Restore options**, you can't easily change the schema during a standard restore if the backup has hardcoded schema names.
5. **The trick:** Restore the backup to `public` first, then rename the schema:

```
ALTER SCHEMA public RENAME TO inventory_schema;
CREATE SCHEMA public; -- Recreate the empty public schema for your local
tables
```

2. Create the Native Foreign Key

Now that `orders` (in `public`) and `products` (in `inventory_schema`) are in the same database, you can link them.

Run this in your Query Tool:

```
-- Link local Sales to the restored Inventory data
ALTER TABLE public.orders
ADD CONSTRAINT fk_order_product
FOREIGN KEY (product_id)
REFERENCES inventory_schema.products(id)
ON DELETE RESTRICT; -- This prevents deleting products that have orders
```

The Resulting SQL Architecture

You no longer need "Soft Keys." You use standard, high-performance SQL:

```
-- Joining across schemas (Native & Fast)
SELECT
    o.order_id,
    p.name as item_name
FROM public.orders o
JOIN inventory_schema.products p ON o.product_id = p.id;
```

Comparison: FDW vs. Cross-Schema

Feature	Two Databases (FDW)	Two Schemas (One DB)
Foreign Keys	Simulated (Triggers/Soft Keys)	**Native & Enforced**
Integrity	High (if using triggers)	**Perfect (Built-in)**
Setup	Complex (User mappings, servers)	**Simple (Standard SQL)**
Isolation	Best (Separate files/processes)	Good (Permissions/Roles)
Backup	Must backup two files	**One file backups everything**

Final Recommendation

If you have the choice, **restoring into a schema within the same database is significantly better** for application development. It eliminates the complexity of the Foreign Data Wrapper and ensures your data can never become "orphaned" or corrupted.

Only use the Two-Database (FDW) approach if:

- The databases are so large they require separate physical disks.
- Two completely different companies/teams manage the servers.

- You are forbidden from merging the data into one instance.

End of Guide.
